Stomatal Conductance of Eight Grain Sorghum Lines Varying in Transpiration Efficiency

Introduction

Plant transpiration efficiency (TE), the ratio of total biomass or carbon assimilation to water transpired, influences crop productivity. Stomatal conductance (g_s) influences photosynthesis (A) and transpiration (T) rates. Does this influence alter transpiration efficiency? If so, do genotypes differ in these effects? Screening of 400 grain sorghum accessions (a micro-lysimetric method under greenhouse condition) indicated transpiration efficiency differed among genotypes (Xin and Aiken, 2006). Do these genotypes differ in stomatal conductance, with implications for transpiration efficiency?

Objective

Evaluate variation for assimilation, stomatal conductance and transpiration efficiency among grain sorghum lines which are expected to differ in TE.

Procedure

Gas exchange measurements of selected grain sorghum accessions were evaluated for differences in g_s, A, TE and Ci (leaf internal CO₂ concentration), under standard conditions.

Plant Material:

The following sets of sorghum lines were selected for the study, representing extremes in the range of TE from a greenhouse screening trial (Xin and Aiken, 2006).

Growth environment:

Differences in stomatal conductance, among the sorghum lines, were evaluated in two field studies.

Irrigated field

Sorghum lines were grown on a deep silt loam soil (Aridic Argiustolls) in four replicated (1.4m*5.6m) field plots with two levels of irrigation and recommended soil fertility level (Fig.1).

Field micro-lysimeters:

Sorghum lines were grown in four replicated micro plots (0.7m*0.07m). Seeds were placed in 1.3 L pots filled with potting mix and saturated with nutrient solution (Fig. 2). Evaporation was minimized by enclosing pots in gaspermeable plastic bags. When the seedlings reached second-leaf (V2) vegetative stage, pots were moved from greenhouse and were placed in a container which was buried in the soil to a depth equivalent to the soil surface. Water was added to the potting mix to maintain relative water content greater than 75%

Leaf gas exchange

Leaf gas exchange measurements (LI-COR LI-6400 portable photosynthesis system) supported the calculation of photosynthesis (A), stomatal conductance (g_s) and leaf internal CO₂ partial pressure (Ci). Standard measurement condition included CO₂ partial pressure (Ca) at 370 μ mol mol⁻¹, temperature of 30 °C, photosynthetic photon flux density of 1200 µmol m⁻² s⁻¹ and vapor pressure deficit at 2.5-3.1 kPa. Measurements were made after the youngest mature leaf had adjusted to cuvette conditions, typically after 15 minutes. Measurements were completed for lines grown in field micro-lysimeters at the six-leaf (V6_{FL}) vegetative stage and at the six-leaf (V6_F) and the ten-leaf $(V10_F)$ stage for lines grown in field study (data from irrigated treatment presented here).

Figure1. Gas exchange measurement of sorghum grown in the irrigated field condition.

Figure 2. Gas exchange measurement of sorghum grown in micro-lysimeters under field conditions.

Analysis:

Intrinsic transpiration efficiency (Tanner and Sinclair, 1983) was calculated from diffusion equations for assimilation (1) and transpiration (2)

 $A = (Ca-Ci) g_{s CO2}$

 $T = (e_1^* - e_a) g_{s H20}$

Therefore, by dividing equation 1 by equation 2, and solving for the assimilation driving gradient, we obtain an expression for transpiration efficiency normalized by vapor pressure deficit (nTE), k (Ca-Ci)= $\underline{A} (\underline{e_l}^* - \underline{e_a})$

where k accounts for the ratio of stomatal conductance of CO_2 ($g_{s CO2}$) and H_2O ($g_{s H20}$), e_1^* is the saturation vapor pressure at leaf temperature, e_a is the ambient vapor pressure and $(e_1^* e_a)$ is the vapor pressure deficit.

Response variables were analyzed as randomized complete block design by SAS using Duncan's multiple range test for means comparison

The following table represent the statistical comparison of $g_{s H20}$, A, Ci, and nTE for the lines measured at standard condition in $V6_{FI}$ and $V6_{FI}$ and $V10_{FI}$.

Table. Means of stomatal conductance, assimilation, leaf internal [CO2] and intrinsic transpiration efficiency for sorghum plants of four replicated plots at six-leaf stage in field lysimeters (V6_{FI}) and six- and ten-leaf stages in field (V6_F and V10_F).

RMSE is the root mean square error. DMRT is the critical value using Duncan's multiple range test and standard error for means comparison.

Stomatal conductance differed among lines in isolated cases. However, no consistent difference among lines in g, was evident. In contrast, we observed consistent trends for Ci, A and nTE which differed for two lines. PI 257309 tended to have greatest Ci, least A and nTE while PI 533946 tended to have least Ci, greatest A and

Measurements combined across lines and environment illustrate a linear relationship between Ci and nTE. (see Fig. 3)

Figure 3. Intrinsic transpiration efficiency is plotted in relation to leaf internal CO₂ for selected sorghum lines, expected to differ in transpiration efficiency. Measurements, under standard conditions, represent means of four replicates, observed at $V6_{FL}$ (circles) $V6_{F}$ (squares) and $V10_{F}$ (triangles).

Since the driving gradient (Ca-Ci) was similar among the lines, we attribute differences in assimilation to g_s as indicated in equation 1. Similarly, we expect differences in g_s to alter transpiration rates, as the driving gradient $(e_1^* - e_a)$ was similar under standard measurement conditions. Under conditions of similar driving gradients, g_s accounted for differences in assimilation and is expected to account for the differences in transpiration.

However, when it comes to intrinsic transpiration efficiency, g_s disappears (equation 3). The ratio of stomatal conductances for CO₂ and H₂0 reduces to a constant (k) in our expression for intrinsic transpiration efficiency (nTE), similar to the result derived by Sinclair and Tanner (1983). Leaf internal CO₂, setting the driving gradient for assimilation, also drives nTE, as illustrated by the contrasting trends of PI 533946 and PI 257309.

The ratio of Ci/Ca observed in these studies (0.18 to 0.27 for all but three observations) was substantially less than that reported by Bunce (2005) for several C4 species (0.55), but near the lower range of values (0.27 to 0.50) reported for grain sorghum by Premachandra et al., (1994). We presume this indicates a greater degree of transpiration efficiency for these lines.
